**Abstract.** Nuclear regions of galaxies generally host a mixture of components with different excitation, composition, and kinematics. Derivation of emission line ratios and kinematics could then be misleading, if due correction is not made for the limited spatial and spectral resolutions of the observations. The aim of this paper is to demonstrate, with application to a long slit spectrum of the Seyfert 2 galaxy NGC 1358, how line intensities and velocities, together with modelling and knowledge of the point spread function, may be used to resolve the differing structures. In the situation outlined, the observed kinematics differs for different spectral lines. From the observed intensity and velocity distributions of a number of spectral lines and with some reasonable assumptions to diminish the number of free parameters, the true line ratios and velocity structures may be deduced. A preliminary solution for the nuclear structure of NGC 1358 is obtained, involving a nuclear point source and an emerging outflow of high excitation with a post shock cloud, as well as a nuclear emission line disk rotating in the potential of a stellar bulge and expressing a radial excitation gradient. The method results in a likely scenario for the nuclear structure of NGC 1358. For definitive results an extrapolation of the method to two dimensions combined with the use of integral field spectroscopy will generally be necessary.

**Keywords.** methods: data analysis, galaxies: kinematics and dynamics, galaxies: structure

## 1. Overview

The nuclear and circumnuclear activity of galaxies generally involves the interplay between a number of different components and phenomena, e.g. a central active source surrounded by an absorbing torus, a rotating central bulge, outflowing jets, flowing streams due to the action of a bar, or even merging. To separate these different components and derive their respective line ratios and kinematic behaviour is generally difficult due to the limited spatial and spectroscopic resolution available. On the other hand, such a separation is crucial to the analysis of the structures and physical processes involved in the nuclear region and their roles in galaxy evolution. Then, as to be demonstrated here, such a separation could benefit by considering the differences of the velocities observed for different spectral lines and be eased by models of the activity, smoothed with the point spread function (PSF) and fitted to the observations. Evidently, to yield the best results this should require an integral field spectrum obtained at the best available spatial and spectral resolution.

NGC 1358 is a barred Sa galaxy hosting an active galactic nucleus at a heliocentric velocity of  $\approx 4100 \text{ km s}^{-1}$ , included in the sample of Ulvestad & Wilson (1989) as a Seyfert 2. It attracted our attention because of its remarkable circumnuclear kinematics (Dumas et al. 2007, Lindblad et al. 2010).

## 2. Modelling

An explanation for the differences in velocity behaviour between the various emission lines would be that the whole central region consists of different gaseous components with different velocity behaviour, different excitation, and different dust absorption, and thus different sets of line ratios. Smoothed by the PSF, different distortions of the velocity field for the different lines will result. Assume that the region considered covers  $N$  pixels and contains  $K$  separate structural components, each with its own line ratios and set of velocities. If  $J_i^{(\lambda)}$  and  $V_i^{(\lambda)}$  are the observed line intensities and velocities at pixel number  $i$  of a line with wavelength  $\lambda$ , we have

$$J_i^{(\lambda)} = \sum_j \sum_k I_{kj}^{(\lambda)} p(i-j) \quad \text{and} \quad V_i^{(\lambda)} = \frac{1}{J_i^{(\lambda)}} \sum_j \sum_k v_{kj} I_{kj}^{(\lambda)} p(i-j),$$

where  $I_{kj}^{(\lambda)}$  is the intrinsic intensity, in the line  $\lambda$ , of the component  $k = (1, \dots, K)$  at the pixel  $j$ , and  $v_{kj}$  the corresponding velocity, which is supposed independent of  $\lambda$ , and  $p(x)$  the PSF. If  $L$  is the number of lines measured, we have in the general case  $KN(L+1)$  unknown and  $2NL$  equations. In the simplest case, where we only consider one component ( $K=1$ ), we have enough equations to solve for the unknown intensities and velocities for each  $\lambda$ , which can be made by CLEAN-like algorithms (Högbom 1974). Further details and application to the spectra from NGC 1358 are given in Lindblad et al. (2010). The model has the following features:

a) A spherical stellar bulge with central position coinciding with that of the continuum maximum, being the sum of two exponential spheres with mass distributions computed using the relation (2–170) of Binney & Tremaine (1987). The spheres have scale lengths  $0''.7$  and  $4''.0$  respectively, and a mass ratio of 4:1. We have, somewhat ad hoc, assumed the intensities in the emission line disk to be the sum of two exponential disks with the same scale lengths as the bulge (here called Disk 1 and Disk 2), thus representing the inner and outer part of the total emission line disk.

b) A central emission line point source coinciding with the centre of the bulge and the emission line disk and at rest with respect to that centre. The redshift of this centre is a free parameter.

c) A gas flow, here called the "jet", seen from the nucleus out to 5 pixels ( $1''.3$ ) from the nucleus with constant line of sight velocity  $-214 \text{ km s}^{-1}$  with respect to the point source, which was the velocity of the "fainter" component relative to the "stronger" as seen in high spatial resolution spectra from the HST of the very nucleus.

d) High positive velocities are necessary to reproduce the sharp rise of the rotation curves at the end of the jet around  $+2''$  from the centre. We call this apparently post shock feature the "Cloud".

The resulting intensities and velocities are convolved with the observed PSF. The free parameters are then varied until satisfactory fits to the observed velocities and intensities have been obtained (see Lindblad et al. 2010).

## 3. Conclusion

Our model (Fig. 1) resolves the nuclear structure of NGC 1358 into (1) a central unresolved emission line source (the Nucleus), (2) a  $1''.3$  long jet emerging from the nucleus with a line of sight velocity of  $-214 \text{ km s}^{-1}$ , (3) a spherical nuclear stellar bulge containing a rotating emission line disk inclined to the stellar kinematic symmetry plane of the bulge, (4) an emission line region (the Cloud) outside the jet with positive velocity as the emission line disk. There is no room for and no need for a counter-jet in

**Figure 1.** Best model fit to the emission line intensities and line of sight velocities. The dotted line indicates the derived redshift of the nuclear source. East is to the right.

our model. Then the true nuclear redshift must be higher than the observed one. This best fit gives an observed redshift of the central source of  $4100 \text{ km s}^{-1}$ , or  $4089 \text{ km s}^{-1}$  with heliocentric velocity correction. The total  $M \times \sin^2(i)$  of the bulge is determined essentially by the velocities of  $\text{H}\alpha$  and  $[\text{N II}]$  at the distance  $-6''$  from the centre. The best fit gives  $M \times \sin^2(i) = 14 \times 10^9 M_{\odot}$ . Figure 1 shows that the velocities and intensities have been reproduced with fair accuracy within this nuclear region. The  $\text{H}\beta$  intensities are too weak and uncertain to give a unique solution in the present case.

With the emission line fluxes for these structures we are able to set up the Starburst-AGN diagnostic diagrams introduced by Baldwin, Phillips & Terlevich (1981). Figure 2 shows the diagnostic diagram  $[\text{O III}]/\text{H}\beta$  versus  $[\text{N II}]/\text{H}\alpha$  where the  $[\text{O III}]/\text{H}\beta$  ratio is derived from  $[\text{O III}]/\text{H}\alpha$  assuming large optical depth, referred to as Case B described in chapter 4.2 of Osterbrock (1989). Accordingly, for an electron temperature of 10000 K, the  $\text{H}\alpha/\text{H}\beta$  is 2.87, which we note is not much different from the case when the gas is assumed to be optically thin. As evident, the nuclear source and the jet fall in the region of highly excited AGNs, while the inner disk and the cloud fall close to the region of liners. The ratios  $[\text{N II}]/\text{H}\alpha$  places the outer part of the nuclear disk and the spiral arms in the HII region domain.

The contribution from the underlying  $\text{H}\alpha$  and  $\text{H}\beta$  absorption lines only change the derived emission line ratios marginally. However, the effect of reddening has not been taken into account in the emission ratios presented in Fig. 2. As we have used the unreddened ratio  $\text{H}\alpha/\text{H}\beta$ , our derived  $[\text{O III}]/\text{H}\beta$  ratios presented in the diagram are lower limits in

**Figure 2.** Line ratio diagnostics derived from our ESO spectra. The solid curve shows the Starburst-AGN separation lines of Kewley et al. (2001), with the shaded region indicating their sample galaxies.

the presence of reddening. This is an effect that favours our conclusions about the nature of the components (further details in Lindblad et al. 2010).

We argue that, with this analysis, we have made a step towards a resolution of the nuclear region of NGC 1358 into a number of different components with different velocity behaviour and excitation, where a summary of the results are seen in Fig. 2. The differing velocities in the different lines give strong constraints for the line ratios. Experiments with our model, for example, shows that it is the weakness of [O III] in the Cloud and nuclear disk that causes the dip in velocity of the Eastern part of the rotation curve to be deeper in [O III] and the [O III] rotation curve to be flatter on both sides. The main ambiguity with the model presented here is the difference in systemic velocity of the bulge and outer disk relative to the nucleus and nuclear emission line disk, as well as the relation of the Cloud to the emission line disk and to the bulge. The Cloud, although introduced in a somewhat ad hoc fashion, could be a component that resides in the emission line disk. Of course, to get all necessary information about the velocities and spatial distribution of the different components from an isolated spectrum is futile, because i.a. of the unknown influence due to the point spread function from sources outside the slit. By adding more slits, there is still a difficulty to obtain an accurate and complete coverage (Lindblad et al. 1996). Obviously, the ideal is an integral field spectrometer and an extension of the method to a two-dimensional treatment covering the entire region of interest.
